ABSTRACT: The paper concerns engineering design governed by multiple objective criteria that are in conflict and compete for available resources (material, financial, etc.). A multicriteria decision making (MCDM) strategy is presented that employs a tradeoff-analysis technique to identify compromise-design solutions that mutually satisfy the competing criteria in a Pareto-optimal sense. The concepts are initially illustrated in detail for a design governed by \( n=2 \) conflicting criteria. Curve-fitting, equation-discovery and equation-solving software are employed to find competitive general equilibrium states corresponding to Pareto-tradeoff designs of a flexural plate governed by conflicting weight and deflection criteria. The MCDM strategy is then extended to designs involving more than two conflicting criteria, and is applied for a bridge maintenance plan design governed by \( n=3 \) criteria. The paper concludes with a discussion of the application of the MCDM strategy to designs involving \( n=4 \) and \( n=11 \) conflicting criteria.

KEYWORDS: multicriteria design engineering, Pareto optimization, Pareto trade-off.

1 INTRODUCTION

Engineering design is generally governed by multiple conflicting criteria, which requires the designer to look for good compromise designs by performing tradeoff studies between them. As the competing criteria are often non-commensurable and their relative importance is generally not easy to establish, this suggests the use of non-dominated optimization to identify a set of designs that are equal-rank optimal in the sense that no design in the set is dominated by any other feasible design for all criteria. This approach is referred to as ‘Pareto’ optimization and has been extensively applied in the literature concerned with multicriteria engineering design (e.g., Osyczka 1984, Koski 1994, Khajehpour 2001, Grierson & Khajehpour 2002).

A Pareto optimization problem involving \( n \) conflicting objective criteria expressed as explicit or implicit functions \( f_i(z) \) of design variables \( z \) \((i=1,2,...,n)\), can be concisely stated as:

Minimize \( \{ f_1(z), f_2(z),..., f_n(z) \} \); Subject to \( z \in \Omega \) \hspace{1cm} (1)

where \( \Omega \) is the feasible design space. A design \( z^* \in \Omega \) is a Pareto-optimal solution to the problem posed by Eq.(1) if there does not exist any other design \( z \in \Omega \) such that \( f_i(z) \leq f_i(z^*) \) for \( i=1,2,...,n \) with \( f_j(z) < f_j(z^*) \) for at least one criterion. The number of Pareto-optimal design solutions to Eq.(1) can be quite large, however, and it is yet necessary to select the best compromise design(s) from among them.

For example, consider the simply-supported plate with uniformly distributed loading shown in Figure 1. It is required to design the plate for the two conflicting criteria to minimize structural weight \( f_1(z) = W \) and midpoint deflection \( f_2(z) = \Delta \), for variables \( z \) taken as the thicknesses of pre-specified zones of the plate (see Koski 1994 for details). For any plate design \( z^* \), its weight \( W^* \) is given by the explicit function \( f_1(z^*) \) while its midspan deflection \( \Delta^* \) is given by the implicit \(^2\) function \( f_2(z^*) \).

\(^1\) \hspace{1cm} n-dimensional Euclidean space

\(^2\) \hspace{1cm} \( f_2(z^*) = \Delta^* \) implies deformation analysis of plate design \( z^* \) to find midpoint deflection \( \Delta^* \)
Table 1. The ten Pareto designs define the Pareto curve in Figure 2; in fact, any one of the theoretically infinite number of points along this curve corresponds to a Pareto design. Therefore, it essentially remains to select a good-quality compromise plate design from among a theoretically infinite set of Pareto designs.

Figure 2. Pareto Flexural Plate Designs (Koski 1994).

2 TWO-DIMENSIONAL MULTICRITERIA DECISION MAKING

Consider a scenario in which two designers $A$ and $B$ are bargaining with each other to achieve an optimal tradeoff between $n=2$ competing criteria represented by two vectors of known values $(f_1, f_2)$ found through Eq. (1) to define a set of Pareto designs for an engineered artifact (e.g., columns 2 and 3 of Table 1 for the flexural plate design). As the criteria are often non-commensurable and may have large differences in their numerical values, it is convenient to normalized their values as $x = f_1/f_1^\text{max}$ and $y = f_2/f_2^\text{max}$ (e.g., columns 4 and 5 of Table 1). With reference to the Pareto curve in Figure 2, for example, the corresponding normalized Pareto curve is as shown in Figure 3, where the maximum value for each of the two normalized criteria is unity.

Suppose that designer $A$ is the advocate for the first criterion to minimize the (normalized) weight $x$ and, therefore, that designer $B$ is the advocate for the second criterion to minimize the (normalized) deflection $y$. Assume that designer $A$ initially begins the bargaining session with the largest weight $x^\text{max} = 1$, and that she considers making a tradeoff between the two criteria defined by the (absolute) value of the slope of the terms-of-trade line shown in Figure 3 passing through her initial point $(1,0)$. To that end, she would choose to trade at an intersection point of the trade line and the normalized Pareto curve so as to comply with the basic principles (structural, mechanical, financial, etc.) governing the feasibility of the Pareto designs. Moreover, if there is more than one such intersection point, as is the case in Figure 3, designer $A$ would choose to trade at that point for which the greatest decrease in weight occurs; i.e., she would trade at point $E$ in Figure 3 by exchanging $1-x$ units of weight for $y$ units of deflection. Before any such tradeoff can take place, however, the trading preferences of designer $B$ must also be accounted for as in the following.

Figure 3. Two-Criteria Tradeoff.

We can draw a diagram similar to Figure 3 for designer $B$ by supposing that he initially begins the bargaining session with the largest deflection $y^\text{max} = 1$. Upon doing that, the competitive equilibrium of the two-designer and two-criterion tradeoff scenario can be analytically investigated.
by constructing the Edgeworth-Grierson unit square\(^1\) (E-G square) in Figure 4. The origins for designers \(A\) and \(B\) are \(0_A\) and \(0_B\), respectively (note that designer \(B\)'s axes are inverted since they are drawn with respect to origin \(0_B\)). Their initial bargaining points \(A(1,0)\) and \(B(0,1)\) are both located at the lower right-hand corner of the unit square. Designer \(A\)'s Pareto curve \(PC_A\) is a plot of data points \((x, y)\) in the fourth and fifth columns of Table 1, while designer \(B\)'s Pareto curve \(PC_B\) is a plot of data points \((1-x, 1-y)\) in the last two columns of Table 1.

Hence, from the last two columns of Table 1, designer \(B\)'s Pareto curve \(PC_B\) is represented by the function,

\[17.15(1-x)^2(1-y) - 1.1(1-y) - 1 = 0\] \(\text{(3)}\)

Upon applying simultaneous equation-solving software (MatLab 2005), Eqs. (2) and (3) are solved to find the two roots \((x_0^*, y_0^*) = (0.367, 0.827)\) and \((x_0^*, y_0^*) = (0.633, 0.173)\). That is, the \((x, y)\) coordinates of the two equilibrium points are \(E_0(0.367, 0.827)\) and \(E_0(0.633, 0.173)\).

Equilibrium point \(E_0\) corresponds to a plate design intermediate to designs 2 and 3 in Table 1 that has weight \(f_i^* = W = (0.367)(112.3) = 41.21\) kg and deflection \(\delta_i^* = \Delta = (0.827)(2.73) = 2.26\) mm, while point \(E_5\) corresponds to a plate design intermediate to designs 7 and 8 in Table 1 that has weight \(f_i^* = W = (0.633)(112.3) = 71.09\) kg and deflection \(\delta_i^* = \Delta = (0.173)(2.73) = 0.472\) mm. While these two plate designs each represent a Pareto tradeoff between the competing weight and deflection criteria, they are not Pareto comparable between themselves. It yet remains for the designers to make a final selection between the two designs according to their preferences.

As the advocate for the weight criterion, designer \(A\) will opt for the plate design at point \(E_0\) because it has the least weight. However, as the advocate for the deflection criterion, designer \(B\) will alternatively prefer the plate design at point \(E_0\) because it has the least deflection. This dilemma is overcome if the two designers agree to act as a team that makes a compromise selection of one of the two designs. In effect, therefore, the MCDM strategy has served to significantly reduce the number of Pareto designs from which the final design selection is made based solely on designer preference (i.e., only two designs for this example).

### 3 PARETO DATA REQUIREMENTS

The MCDM tradeoff analysis depicted in Figure 4 implies the Pareto data \(f_i^*(f_{i\min}, ..., f_{i\max})\)\(^3\) for each competing criterion \(i\) satisfies certain conditions that ensure a competitive equilibrium point \(E\) exists within the boundary of the E-G square.

For an equilibrium point \(E\) to be within the boundary, it is necessary that \(f_{i\max}\) be greater than zero. This condition is naturally satisfied for most engineering criteria. If originally \(f_{i\min} \leq 0\), as Pareto optimization is ordinal it is possible to make an additive uniform shift \(\delta_i^*\) of the floating-point data \(f_i\) to make \(f_{i\min} + \delta_i^* > 0\) without changing the Pareto nature of the data; i.e., uniformly add,

\[\delta_i^* > |f_{i\min}| \text{ if } f_{i\min} \leq 0 \text{; otherwise } \delta_i^* = 0\] \(\text{(4)}\)

For an equilibrium point \(E\) to exist, it is sufficient that the ratio \(f_{i\min}/f_{i\max}\) be less than or equal to \(1-\sqrt{2}/2 = 0.293\).\(^5\) This condition is naturally satisfied for some engineering

---

\(^1\) English economist F. Y. Edgeworth (1845-1926) was among the first to use a similar analytical tool known as the Edgeworth box to investigate the competitive equilibrium of a two-consumer and two-good exchange economy.

\(^2\) Note that in Table 1 and Eqs. (2) & (3) the coordinates \(x\) and \(y\) are measured from the origin point \(O\) in Figure 4; i.e., \(x = x_4\) and \(y = y_4\), and therefore \((1-x) = x_8\) and \((1-y) = y_8\).

\(^3\) The limiting case when the Pareto curve is circular with radius \(\sqrt{2}/2\), such that a single equilibrium point \(E(0.5, 0.5)\) exists at midpoint of the E-G square.
criteria. If originally \( f_i^{\min}/f_i^{\max} > 1 - \sqrt{2}/2 \), as Pareto optimization is ordinal it is possible to make a subtractive uniform shift \( \delta_i \) of the floating-point data \( f_i \) to make \( (f_i^{\min} - \delta_i)/(f_i^{\max} - \delta_i) = 1 - \sqrt{2}/2 \) without changing the Pareto nature of the data; i.e., uniformly subtract,

\[
\delta_i = f_i^{\max} - \sqrt{2}(f_i^{\max} - f_i^{\min}) \text{ if } f_i^{\min}/f_i^{\max} > 0.293; \text{ otherwise } \delta_i = 0 \tag{5}
\]

From the foregoing, the existence of a competitive equilibrium point \( E \) within the boundary of the E-G square is ensured whenever the original or shifted Pareto data \( f_i^{\min}, ..., f_i^{\max} \) for each competing criterion \( i \) is such that,

\[
0 < f_i^{\min} \leq 0.293 f_i^{\max} \tag{6}
\]

where the lower bound is a necessary and sufficient condition, while the upper bound is a sufficient condition. That the upper bound in Eq.(6) is not a necessary condition is evidenced by the flexural plate example, for which the tradeoff analysis determined that two equilibrium points exist even though for the weight criterion the ratio \( f_i^{\min}/f_i^{\max} = 39.4/112.3 = 0.351 > 0.293 \) (see Table 1). However, the existence of equilibrium points in such circumstances depends on the shape of the Pareto curve and cannot be proved in general.

Whenever the original Pareto data \( f_i^{\min}, ..., f_i^{\max} \) for any criterion \( i \) does not satisfy the upper bound in Eq.(6), it is recommended that the data be shifted by uniformly subtracting \( \delta_i \) defined by Eq.(5) so that Eq.(6) is satisfied. Then, after the MCDM tradeoff analysis is conducted to find each equilibrium point \( E \) and corresponding criteria values \( f_i^* \) \((i = 1, 2, 3) \), the Pareto-tradeoff design value for each criterion \( i \) is found as,

\[
f_i^* = f_i^{**} + \delta_i \tag{7}
\]

For the flexural plate, for example, after shifting the Pareto data \( f_i \) for the weight criterion by uniformly subtracting \( \delta_i = 112.3 - \sqrt{2}(112.3 - 39.4) = 9.205 \) kg (see Table 1)\(^6\), the tradeoff analysis determines the two equilibrium points \( E_0(0.305, 0.878) \) and \( E_0(0.695, 0.123) \). Equilibrium point \( E_0 \) corresponds to weight \( f_1^{**} = (0.305)(112.3 - 9.205) = 31.44 \) kg and deflection \( f_2^* = (0.878)(2.73) = 2.40 \) mm, while point \( E_0 \) corresponds to weight \( f_1^{**} = (0.695)(112.3 - 9.205) = 71.65 \) kg and deflection \( f_2^* = (0.123)(2.73) = 0.336 \) mm. Therefore, from Eq.(7), the Pareto-tradeoff plate design corresponding to point \( E_0 \) is intermediate to designs 2 and 3 in Table 1 with weight \( f_1^* = f_1^{**} + \delta_i = 31.44 + 9.205 = 40.65 \) kg and deflection \( f_2^* = f_2^{**} + \delta_i = 2.40 + 0 = 2.40 \) mm, while the Pareto-tradeoff design corresponding to point \( E_0 \) is intermediate to designs 8 and 9 in Table 1 with weight \( f_1^* = f_1^{**} + \delta_i = 71.65 + 9.205 = 80.86 \) kg and deflection \( f_2^* = f_2^{**} + \delta_i = 0.336 + 0 = 0.336 \) mm.

It is observed for the flexural plate that the original and shifted Pareto-tradeoff designs at point \( E_0 \) are almost identical (i.e., 41.21 versus 40.65 kg weight, and 2.26 versus 2.40 mm deflection), while those at point \( E_0 \) are moderately different (i.e., 71.09 versus 80.86 kg weight, and 0.472 versus 0.336 mm deflection). In fact, it can be argued that the tradeoff design results are more for accurate for the shifted Pareto data as it more representative of that part of the data which essentially determines its Pareto optimality.\(^7\)

Finally, it is observed that it is not possible to shift the Pareto data for any criterion \( i \) for which \( (f_i^{\max} - f_i^{\min})/f_i^{\max} < \varepsilon \), where \( \varepsilon \) is the adopted tolerance for setting floating-point numerals to zero.\(^8\) Such data is almost perfectly uniform, is not in meaningful conflict with the other objective criteria for the design, and can be assigned the fixed objective value \( f_i^* = (f_i^{\max} + f_i^{\min})/2 \) without affecting the remaining Pareto data set.

4 N-DIMENSIONAL MULTICRITERIA DECISION MAKING

The MCDM tradeoff strategy is generalized in the following to design problems governed by more than two conflicting criteria in competition for resources. Consider a design governed by \( n > 2 \) competing criteria represented by \( m \)-dimensional vectors \( f_1, f_2, ..., f_n \) of known values found through solution of Eq.(1) to define a Pareto set of \( m \) designs. The Pareto vectors are each normalized over the [0,1] range as \( x_i = f_i f_i^{\max} (i = 1, 2, ..., n) \) to achieve the dimensionless and therefore commensurable data \( x_1, x_2, ..., x_n \).

By definition, a tradeoff can be made between only two criteria at any one time. For \( n > 2 \) criteria, this study investigates the tradeoff between each primary criterion and a corresponding aggregate criterion formed from the remaining \( n-1 \) criteria. The \( m \)-dimensional vectors \( x_i \) \((i = 1, 2, ..., n) \) are initially employed to create \( n \) pairs of vectors \( (x_i, y_i) \) where, for each pair, \( x_i \) is the vector of primary criterion values while \( y_i \) is a corresponding vector of aggregate criterion values found as,

\[
y_i = \prod_j x_j \quad (j = 1, 2, ..., n) \quad : \quad n \neq i \tag{8}
\]

For example, for a design problem governed by \( n = 3 \) conflicting criteria defined by Pareto vectors \( x_1, x_2, x_3 \) and \( x_4 \), evaluation of Eq.(8) for \( i = 1, 2, 3 \) yields the following \( n = 3 \)

---

\(^6\) Note that the Pareto data \( f_i \) for the deflection criterion is not shifted since, from Table 1, \( f_i^{\min}/f_i^{\max} = 0.175/2.73 = 0.064 < 0.293 \) and, therefore, \( \delta_i = 0 \) from Eq.(5).

\(^7\) To put this statement in perspective, suppose a Pareto vector of original data for a financial objective criterion (e.g., minimize capital cost) consists of elements that are all between one and two million currency units (e.g., Dollar, Euro, etc.). One million currency units can be uniformly subtracted from all elements to create a Pareto vector of shifted data whose elements are all of the order of the thousands of currency units which determine the Pareto optimality of the original data.

\(^8\) For example, \( \varepsilon = 10^{-4} > 0.9999 \times 10^{-4} \approx 0 \).
pairs of vectors: \((x_1, y_1) = (x_1, x_2, x_3)\), \((x_2, y_2) = (x_2, x_3, x_4)\) and \((x_3, y_3) = (x_3, x_4, x_5)\).

Each \(y_i\) vector represents an aggregate criterion in conflict with a corresponding \(x_i\) vector representing a primary criterion. As the primary vectors \(x_i\) are normalized over the \([0,1]\) range, it follows from Eq.(8) that the aggregate vectors \(y_i\) are similarly normalized and are thus commensurable among themselves and with the \(x_i\) vectors. However, even though the \(y_i\) vectors are formed from the Pareto set of \(x_i\) vectors, it does not follow that each pair of vectors \((x_i, y_i)\) constitutes a Pareto set. As this is a necessary condition for application of the MCDM tradeoff strategy, a Pareto filter\(^9\) is applied in turn to each of the \(n\) pairs of \(m\)-dimensional vectors \(x_i\) and \(y_i\) to retain a corresponding Pareto pair of reduced-dimension vectors \((x_i, y_i)\), along with a record of the indices of the retained designs. As it is unlikely that the retained designs are the same for all \(n\) Pareto pairs, and as this is necessary to facilitate comparative interpretation of the results of the \(n\) tradeoff analyses, a design-index filter is further applied to retain only the \(p < m\) designs that are common to all \(n\) Pareto pairs.\(^{10}\) When necessary, \(x_i\) or \(y_i\) vector data is shifted by uniformly subtracting \(\delta_i\) given by Eq.(5) so that Eq.(6) is satisfied (where, here, \(f_i^{\text{max}} = x_i^{\text{max}}\) or \(y_i^{\text{max}}\), and \(f_i^{\text{min}} = x_i^{\text{min}}\) or \(y_i^{\text{min}}\)). Finally, where necessary, the \(p\)-dimensional \(x_i\) and \(y_i\) vectors are normalized as \(x_i^{*} = x_i/x_i^{\text{max}}\) and \(y_i^{*} = y_i/y_i^{\text{max}}\) to restore the data for all \(n\) Pareto pairs to the \([0,1]\) range.

Having the \(n > 2\) Pareto pairs of \(p\)-dimensional vectors \((x_i, y_i)\), the MCDM tradeoff strategy is applied in turn to find for each vector pair \(i\) the two competitive general equilibrium points,

\[
E_{ai}(x_{ai}^*, y_{ai}^*) ; \quad E_{bi}(x_{bi}^*, y_{bi}^*) \quad (i = 1, 2, \ldots, n) \tag{9}
\]

where values \(x_{ai}^*\) and \(x_{bi}^*\) of primary criterion \(i\) represent a Pareto tradeoff with values \(y_{ai}^*\) and \(y_{bi}^*\) of aggregate criterion \(i\), respectively. It remains to select a final good-compromise design from among the \(2n\) designs identified by points \(E_{ai}\) and \(E_{bi}\) (e.g., from among six designs if \(n = 3\); see the following Bridge example).

5 BRIDGE MAINTENANCE PLAN DESIGN

It is required to design a bridge maintenance-intervention plan that exhibits optimal tradeoff between \(n=3\) conflicting objective criteria concerning maintenance life-cycle cost, bridge condition, and bridge safety (Liu & Frangopol 2005). The life-cycle cost criterion involves minimization. The bridge condition criterion involves minimization, as it is represented by a damage-inspection index for which smaller values indicate better conditions.

The safety criterion involves maximization, as it is represented by a load-capacity index for which larger values indicate more safety. The design is formulated as the Pareto optimization problem,

\[
\text{Minimize} \{ f_1(z), f_2(z), f_3(z) \} \quad \text{Subject to } z \in \Omega \tag{10}
\]

where, from Eq.(1), \(z\) are the design variables and \(\Omega\) is the feasible design space. The function \(f_3(z) = \text{life-cycle cost}, \text{while } f_2(z) = \text{condition index, and } f_3(z) = 1/(\text{safety index})^{11}\).

Liu and Frangopol (2005) solved Eq.(10) using a multicriteria genetic algorithm to find three 194x1 vectors \(f_1, f_2, f_3\) representing 194 Pareto designs of the bridge maintenance plan. The corresponding minimum and maximum criteria values, \(f_i^{\text{min}}\) and \(f_i^{\text{max}}\) \((i=1,2,3)\), are listed in Table 2.

</tbody>
</table>

The MCDM strategy is applied to the 194 Pareto designs to identify a total of \(2n=2\times3=6\) Pareto-tradeoff designs, as follows:

1. For the \(f_i^{\text{max}}\) values in Table 2, normalize the 194x1 Pareto vectors \(f_1, f_2, f_3\) over the \([0,1]\) range to create the 194x1 primary vectors \(x_1 = f_1/f_1^{\text{max}}, \quad x_2 = f_2/f_2^{\text{max}}, \quad x_3 = f_3/f_3^{\text{max}}\).

2. From Eq.(8), create the 194x1 aggregate vectors \(y_1 = x_1^2, x_2, x_3^2, y_2 = x_1^2, x_2^2, x_3, y_3 = x_1, x_2, x_3^2\).

3. Apply a Pareto filter to each of the \(i=1, 2, 3\) pairs of 194x1 vectors \((x_i, y_i)\), to create the three corresponding Pareto pairs of: \(80x1\) vectors \((x_1, y_1)\); \(49x1\) vectors \((x_2, y_2)\); \(43x1\) vectors \((x_3, y_3)\).

4. Apply a design-index filter to the three variable-dimension Pareto pairs of vectors \((x_1, y_1); (x_2, y_2); (x_3, y_3)\) created in Step 3, to create the three corresponding common-dimension Pareto pairs of 24x1 vectors \((x_1, y_1); (x_2, y_2); (x_3, y_3)\).

5. For the 24x1 Pareto vectors \((x_1, y_1); (x_2, y_2); (x_3, y_3)\) created in Step 4, calculate the following ratios and observe that vectors \(x_2\) and \(x_3\) do not satisfy the upper bound of Eq.(6):

\[
x_i^{\text{min}}/x_i^{\text{max}} = 0.056/0.974 = 0.057, \quad y_i^{\text{min}}/y_i^{\text{max}} = 0.087/0.977 = 0.089
\]

\(^{11}\) Minimization of \(1/f(z)\) is equivalent maximization of \(f(z)\).
From Eq.(5), uniformly subtract 
\[ \delta_2^- = 0.994 - \sqrt{2(0.994 - 0.450)} = 0.225 \]
from vector \( x_2 \), and
\[ \delta_3^- = 0.993 - \sqrt{2(0.993 - 0.715)} = 0.560 \]
from vector \( x_3 \), to create two new 24x1 Pareto vectors \( x_2' \) and \( x_3' \) that identically satisfy the upper bound of Eq.(6).

For the \( x_i^{\text{max}} \) and \( y_i^{\text{max}} \) values from Steps 5 and 6, normalize the 24x1 vectors \( (x_1, y_1 ; x_2, y_2 ; x_3, y_3) \) created in Steps 4 and 6 over the \([0,1]\) range, to create the Pareto primary-aggregate criteria pairs of 24x1 vectors \( (x_i, y_i) (i=1, 2, 3) \) listed in Table 3 along with the indices of the corresponding 24 designs retained from among the original 194 Pareto designs.

Apply curve-fitting/equation-discovery software (TableCurve2D 2005) for each of the three pairs of Pareto vectors \( (x_i, y_i) \) in Table 3, to find that each of the three corresponding Pareto curves is accurately represented (\( \rho^2 \geq 0.988 \)) by the function,
\[ c_i x_i y_i + d_i y_i - 1 = 0 \quad (i=1,2,3) \]
where:
\[ c_1 = 13.231, \quad c_2 = 5.710, \quad c_3 = 5.611, \]
\[ d_1 = 0.198, \quad d_2 = -0.624, \quad d_3 = -0.634. \]

As for the E-G square, formulate the inverse function,
\[ c_i (1-x_i)(1-y_i) + d_i (1-y_i) - 1 = 0 \quad (i=1,2,3) \]
where:
\[ c_1 = 13.231, \quad c_2 = 5.710, \quad c_3 = 5.611, \]
\[ d_1 = 0.198, \quad d_2 = -0.624, \quad d_3 = -0.634. \]

Apply simultaneous equation-solving software (MatLab 2005) to solve Eqs. (11) and (12), to find for each primary-aggregate criteria pair \( i \) the two competitive general equilibrium points,
\[ E_{ai}(x_{ai}^*, y_{ai}^*) ; E_{bi}(x_{bi}^*, y_{bi}^*) \quad (i=1, 2, 3) \]
where:
\[ x_{a1}^* = 0.0672, \quad y_{a1}^* = 0.9203 ; \quad x_{b1}^* = 0.9328, \quad y_{b1}^* = 0.0797 \]
\[ x_{a2}^* = 0.3743, \quad y_{a2}^* = 0.6609 ; \quad x_{b2}^* = 0.6257, \quad y_{b2}^* = 0.3391 \]
\[ x_{a3}^* = 0.3912, \quad y_{a3}^* = 0.6405 ; \quad x_{b3}^* = 0.6088, \quad y_{b3}^* = 0.3595 \]

To complete the MCDM analysis, account for the normalization parameters \( f_i^{\text{max}} \) and \( x_i^{\text{max}} \) used in Steps 1 and 7, respectively, and the shift parameters \( \delta_i^+ \) used in Step 6, to relate the six primary criteria values \( x_{ai}, x_{bi} \) \( (i=1,2,3) \) found in Step 10 to the six Pareto-tradeoff bridge maintenance plan designs \( f_{i1}, f_{i2}, f_{i3} \) listed in Table 4. Figure 5, consisting of three E-G squares, provides a geometrical interpretation of the MCDM analysis.

The design indices 34, 54, 69, 78, 84 and 179 indicated in Table 4 and Figure 5 refer to the six designs from among the original 194 Pareto designs that are closest to the Pareto-compromise design points defined by Eq.(13); i.e., six bridge maintenance plan designs that represent a Pareto tradeoff between the three competing objective criteria to minimize life-cycle maintenance cost, minimize bridge damage condition, and maximize bridge safety. It yet remains for the designers to make a final selection from among the six designs according to their preferences.

Figure 5. Edgeworth-Grierson tromino12 (Bridge maintenance plan design).
6 PENDING APPLICATIONS OF THE ‘MCDM’ STRATEGY

It is intended to design a multi-story office building that exhibits optimal tradeoff between \( n=4 \) conflicting objective criteria concerning capital cost, life-cycle cost, income revenue and structural safety. The capital cost and life-cycle cost criteria involve minimization, while the revenue and safety criteria involve maximization. The design can be formulated as the Pareto optimization problem,

\[
\text{Minimize} \{ f_1(z), f_2(z), f_3(z), f_4(z) \} \quad \text{Subject to } z \in \Omega \quad (14)
\]

where \( z \) are the design variables and \( \Omega \) is the feasible design space. The function \( f_1(z) = \text{capital cost} \), while \( f_2(z) = \text{life-cycle cost} \), \( f_3(z) = 1/(\text{revenue}) \) and \( f_4(z) = 1/(\text{safety}) \).

Khajehpour and Grierson (2003) solved a similar problem to Eq.(14) using a multicriteria genetic algorithm to find four \( 815 \times 4 \) vectors \( f_1, f_2, f_3, f_4 \) representing 815 Pareto designs of the office building. It yet remains to identify the \( 2n=2\times4=8 \) Pareto tradeoff-compromise designs of the building; i.e., eight building designs from among the 815 Pareto designs that represent a Pareto tradeoff between the four competing objective criteria to minimize capital and life-cycle costs and maximize revenue and safety.

It is intended to design a media centre that exhibits optimal tradeoff between \( n=11 \) conflicting objective criteria concerning building cost and lighting performance. Four of the criteria involve minimization and seven involve maximization. Shea et al (2006) recognized that \( 4.2 \times 10^{38} \) possible designs exist, and applied a multicriteria ant colony optimization method with Pareto filtering to find a large number of Pareto designs. It yet remains to identify the \( 2n=2\times11=22 \) Pareto tradeoff-compromise designs of the media centre; i.e., twenty-two Pareto designs that represent a Pareto tradeoff between the eleven competing objective criteria concerning cost and lighting.

ACKNOWLEDGMENTS

This study is supported by the Natural Science and Engineering Research Council of Canada. For help in preparing the paper text and the computational examples, thanks are due to Kevin Xu, Department of Electrical and Computer Engineering, University of Waterloo, Canada. For insights into the welfare economics principles that underlie the design engineering principles of the study, the author is grateful to Kathleen Rodenburg, Department of Economics, University of Guelph, Canada. The Pareto data for the bridge design example was provided by Dan Frangopol, Department of Civil & Environmental Engineering, Lehigh University, USA.
